ANALYSIS

Testing alternative indicators for biodiversity conservation in old-growth boreal forests: ecology and economics

Abstract

In this study, the performance of biodiversity indicators used in the selection of boreal old-growth forest reserves is assessed. The indicators include beetles, birds, vascular plants, wood-inhabiting fungi, and a specified subgroup of assumed indicator species. Our site selection procedure includes information both on ecological variables and on the economic costs incurred from the ecological survey and the opportunity costs of conservation. Complementarity and scoring procedures in site selection are compared. We show that the use of indicators likely results in a loss of species, and therefore, a complete inventory of biodiversity is necessary if the goal is to maintain all species in the landscape. However, the use of indicators seems to be an economically more efficient practice than to execute a large biodiversity survey for habitat protection in our case study. In general, birds and vascular plants seem better indicators than other taxa. A scoring approach performs better than a complementarity approach for indicator taxa containing a small number of species.

1. Introduction

Setting aside forest areas that are particularly biodiverse is regarded as an efficient way to maintain biodiversity in forest landscapes under commercial use because habitat loss is currently the most serious threat to species and ecosystems (see for example, Fahrig, 2001). The protection of regional biodiversity requires that priority for the protection of individual areas be based on the contribution which the area can make to represent overall biodiversity. However, it may be extremely costly to measure this contribution for all potential sites. Therefore, area selection procedures have to rely on surrogate measures of biodiversity (Faith and Walker, 1996). One standard approach is based on indicator groups of taxa. As a result, choosing the best possible indicators becomes a crucial step in biodiversity maintenance.

How is one to choose a good indicator? In general, indicators should represent key attributes of those ecological properties that are regarded important and that are too difficult or expensive to monitor directly. Several a priori suitability criteria have been proposed

for the selection of indicators (Noss, 1990; McGeoch, 1998). For instance, the data for the indicator should be relatively easy to sample and sort, and the indicator should be sufficiently sensitive to provide an early warning of change, widely applicable, and be independent of sample size. These kinds of criteria can help the selection of indicators for species and higher taxa, but formal tests are required to assess how well the chosen indicators reflect the overall biodiversity.

In this paper, we search for indicators for biodiversity conservation. By using comprehensive background data, we test how well potential indicators perform when selecting boreal old-growth forest areas for protection. We address an ecological aspect that is a representation of biodiversity in the broad sense of all species and also focus on economic cost efficiency. By cost efficiency we mean biodiversity optimisation by selecting a conservation network under a given budget constraint. As resources for conservation are limited, cost efficiency is an important aspect of forest management and forest reserve selection for biodiversity maintenance (e.g., Haight, 1995). To our knowledge, the cost efficiency of biodiversity indicators has been, until now, an unstudied issue (see Gaston, 1996; Flather et al., 1997, and McGeoch, 1998 for reviews on indicator studies). Balmford and Gaston (1999) used, however, a rather similar approach to ours to assess the benefits of high quality biodiversity inventories.

We first study whether taxonomic groups can be used as indicators. We include beetles, birds, vascular plants, and wood-inhabiting fungi, and we test, for example, whether birds can be used as indicators for other taxa. These taxa represent a wide array of species ecologies, dispersal abilities, and life histories in boreal forests. Birds and vascular plants are rather well-known taxa and may therefore be considered generally as potential indicators. Moreover, it is well known that some beetle and wood-inhabiting fungi species require certain structural characteristics of old-growth forests, and thus, these taxa may also be potential indicators. The second class we focus on is the occurrence of a specified subgroup of species (including species of birds, beetles, and fungi), which earlier studies suggest to indicate old-growth forest conditions. We test whether or not they cover the variation in overall species diversity of old-growth forests.

To test these indicators, we develop the following phased method by using site selection models. First, we run the site selection procedures using optimisation algorithms separately for different potential indicators. Second, we execute the optimisation for benchmark selection by using information on all species. Thus, the benchmark selection represents, by assumption, the maximum level of biodiversity in the region at given resources devoted to conservation. Third, we compare the results from indicator-based area selection with the results from site selection based on information on all species to study how well biodiversity become conserved when using information on indicators only. On the basis of this comparison, we end up with a ranking of potential indicators. However, we execute the ranking by using two alternative site selection procedures, the ecological and integrated models. The ecological model uses information on species presence/absence only by maximising biodiversity under a given upper limit for a number of protected sites (Sætersdal et al., 1993; Dobson et al., 1997; Howard et al., 1998; Van Jaarsveld et al., 1998; Reyers et al., 2000; Virolainen et al., 2000), whereas the integrated model explicitly takes into account both economic and ecological aspects of biodiversity by maximising biodiversity under a given budget constraint (Ando et al., 1998, Balmford et al., 2000; Polasky et al., 2001; Juutinen et al., in press). Comparisons between integrated and ecological selections allow us to see if the ranking remains the same when the costs of biodiversity surveys, as well as the opportunity costs of conservation, are incorporated into the procedure.

We use the number of species encompassed in the selected network of forest areas as the criterion for biodiversity assessment in the benchmark models because one of the ultimate long-term goals of the present forest management practices in Fennoscandia is to maintain viable populations of all naturally occurring species in a considered area (Mönkkönen, 1999). Moreover, species richness is a simple and transparent measure, and it is often positively correlated with many other (genetic, taxonomic, functional, etc.) measures of biodiversity (Gaston, 1996). Our data originate from 32 old-growth forest stands in NE Finland within two landscape ecological forest management areas. We use lost harvesting revenues (forest values) as opportunity costs of conservation.
The rest of the paper is organized as follows. In Section 2.1, we present the site selection models and explain how the tests can be executed by comparing the results of indicator models and benchmark models. Data are briefly described in Section 2.2. Section 3 includes the results of indicator tests according to an ecological approach. Section 4 considers the cost efficiency of indicator species. Section 5 is devoted to the assessment of the results. Finally, conclusions are in Section 6.

2. Framework and data

2.1. Biodiversity indicators in site selection

The goal of a forest manager is to select old-growth stands for a conservation network so that the biodiversity function is maximized with given resources available for conservation. A manager has a resource constraint, which can be expressed by a number of stands (or an area constraint) or a budget constraint. We use the former in the ecological and the latter in the integrated model. Cost-effective conservation under a given budget requires that a forest manager will take into account the differences of forest values, e.g., in the form of harvest revenues. The ecological approach implicitly assumes that stands have equal forest values and partially neglects the economic costs of conservation.

For this study, we assume that the only forest management option for biodiversity preservation is the protection of old-growth stands (nontreatment), so that the conservation problem can be formalized by using site selection models. Our models are presented in Table 1. They are classified into two model types named DIV and NUM. The models are based on indicator taxa, and we develop several versions of these models depending on which taxa are sampled for their diversity. The DIV model, which incorporates information on all species, is the benchmark model with which all the other models are compared.

* Site constraint is used in the ecological models (E).
** Budget constraint in the integrated models (I). Notation is explained in Appendix B.
ensures that species $i$ is counted as being represented when at least one of the stands where it occurs is selected. The EDIV model has a site constraint Eq. (3), where $k$ is the given upper limit for the number of stands in the conservation network. The IDIV model has a budget constraint Eq. (4) which requires that the sum of opportunity costs of the stands selected and inventory costs of a given species do not exceed the funds allowable for a conservation network. Note that we treat inventory costs as fixed costs because all the candidate stands have to be surveyed irrespective of how many of them will be protected (see also Balmford and Gaston, 1999). Inventory costs depend only on the considered indicator so that they do not have a direct impact on the selection among stands because the relative values of the stands do not change. The constraint set (5) simply indicates that the choice variables must be binary. Thus, the stands are either protected or harvested and the species are represented or not represented in their entirety.\footnote{The optimisation with all species forms an unbiased benchmark for indicator testing. According to the benchmark model, maximizing the number of species results in solutions where all higher taxa (beetles, birds, fungi, and plants) become represented from the very beginning proportionately to their overall relative species number (see Appendix A). The event has a simple explanation. All stands foster species from all taxa and there is relatively little variation in the relative distribution of species among taxa between stands. On the other hand, the stands, which differ greatly from each other in terms of species distribution among taxa, are the most supplementary options and become selected one after the other.}

The presentation of DIV models is called a maximal coverage problem (MCP, Camm et al., 1996). The models are based on the complementarity concept of forcing to select stands that supplement each other from the viewpoint of species richness.\footnote{The ecological literature uses the word complementarity in this context (May, 1990; Vane-Wright et al., 1991). According to economic concepts, it is, however, a matter of substitutability or total independence (Koskela and Ollikainen, 2001).} The stands are considered as a set, taking into account the spatial interdependence among stands in terms of species representation. Thus, in order to maximize species richness, it is optimal to protect stands where the species composition differs as much as possible. Note, however, that the model is not spatially explicit, as it does not take into account the spatial configuration of the selected stands. Hereafter, we use the concept of complementarity approach to refer to the DIV type models.

If species number in an indicator species group is small, all species may become included into the network after just a very few stands are selected. In such cases, the DIV models can no longer be used to select the remaining stands according to their conservation value. The problem is avoided by using the NUM type model, where stands can be ranked although all species are already covered by the existing conservation area network. In the target function of NUM models, (1), species are counted as many times as they are present in the selected stands. Thus, the NUM models resemble a scoring procedure, and what follows, we use the concept of “scoring approach” to indicate the NUM type models. Scoring means that all stands are given some conservation value, which does not depend on the selected conservation network.\footnote{Because the INUM model has a budget constraint, it may not be possible to select the stands into the network according to a fixed rank. The stands having a high score cannot be protected when their opportunity costs are too large with respect to a given budget. Therefore, in the INUM model, the ranking of stands varies according to the allowable budget, but in the ENUM model, it is fixed.} Thus, scoring omits that the stands are interdependent due to the biodiversity services.

The indicators can be tested with the following procedure. Denote species richness given by the benchmark and indicator models at a given resource constraint ($B$ or $k$) by $Y_{\text{bench}}$ and $Y_{\text{ind}}$, respectively. We are interested in the difference between $Y_{\text{bench}}$ and $Y_{\text{ind}}$, which indicates species loss. In order to know $Y_{\text{ind}}$, we first have to use indicator models to maximize $Z$ and find out the corresponding conservation network at a given resource constraint ($B$ or $k$). For this comparison, we exclude the inventory costs from the integrated models because those are treated as fixed costs. Otherwise, it would not be possible to compare indicator and benchmark results until the budget is high enough to cover the maximum inventory costs and the lowest forest value of the stands. The benchmark model has the biggest inventory costs because it includes all the species. Therefore, in the ecological approach, we use this
comparison to rank the indicators, but in the integrated approach, it only demonstrates whether the use of an indicator can result in species loss (or increased opportunity costs).\textsuperscript{5} In the latter approach, it cannot be used to rank the indicators because the economic rank depends also on the inventory costs. To rank the indicators in economic terms, we compare conservation costs ($C$) at a given level of biodiversity. More precisely, using the previous notation for costs, $C$, we are interested in the difference between $C_{\text{bench}}$ and $C_{\text{ind}}$ at a given level $Y$. Both comparisons are, however, needed to see the differences between ecological and economical ranks.

2.2. Data

The database includes 32 seminatural old-growth forest stands in the middle boreal forest vegetation zone in Finland. Drawing on their age and forest structure, these stands were preselected as the best targets to complement the existing old forest conservation network in the region. We sampled four forest site types, each type including eight stands: xeric coniferous forests (Vaccinium–Myrtillus/Empetrum–Vaccinium type), mesic spruce forests (Vaccinium–Myrtillus type), spruce mires (a heterogenous group of wet site types), and herb-rich spruce-dominated heath forests (Geranium–Dryopteris or Vaccinium–Myrtillus/Geranium–Dryopteris type). These site types cover in practice the whole gradient of forests in this region and represent a fertility gradient ranging from barren pine heaths to herb-rich forests. The sampled species in each stand are beetles (Coleoptera), birds (Aves), wood-inhabiting fungi (Basidomycetes), and vascular plants (Tracheophyta). These taxa were selected to cover a wide array of dispersal potential and life forms in order to yield general results. The data consist of 103 vascular plants, 30 birds, 64 wood-inhabiting fungi, and 435 beetle species, making a total number of species of 632 (see Similä et al., 2002 and Juutinen et al., in press for a more detailed description of the study sites and sampling method).

From the total species set, we separated a subgroup of old-growth forest indicator species based on their known status as old-growth forest specialists. The indicator group includes a total of 42 species of which 14 are wood-inhabiting fungi (Kotiranta and Niemelä, 1996), 5 birds (Väisänen et al., 1998), and 23 beetles (J. Siitonen, personal communication, 2001).

A Finnish forestry planning model, called MELA, was used to calculate the site value (lost revenue from alternative uses) for each stand (Siitonen et al., 1996). MELA calculates the net present value of a forest by approximating Faustmann’s formula; thus, the site value consists both timber and land values. The data on detailed stand characteristics for the forest value calculations were taken from the Finnish Forest and Park Service forestry files. Because the use of total timber and land values would automatically bias the selection of sites under a budget constraint toward small stands, we use unit forest values (€/ha) and treat stands as having equal sizes in the optimisation.

The models also include the inventory costs of the particular species group. The inventory costs are based on the actual time and effort spent to collect the data for that particular group including the travel costs, materials, and working hours for field work and species identification. These costs cannot be calculated for each stand separately because all 32 stands should have been inventoried anyway. Likewise, it is not reasonable to express these costs per hectare because each stand irrespective of its size was sam-

\begin{table}

\end{tabular}
\textsuperscript{a}Includes all inventory costs of beetles, birds, and wood-inhabiting fungi, except that the costs of species identification were reduced to correspond to the lower number of considered old-growth forest species.
\end{table}

\textsuperscript{5} This comparison is an interesting starting point for indicator testing also because it may be possible to use existing inventory data in the optimisation, meaning that the inventory costs can be excluded from the consideration. Moreover, previous studies basing on the ecological approach have used similar comparisons (Howard et al., 1998; Pharo et al., 2000; Reyers et al., 2000; Virolainen et al., 2000).
pled with equal effort. The inventory costs are presented in Table 2.

3. Ecological properties of the indicators

In this section, we test indicators from a purely ecological perspective by analysing how their use in the ecological models is reflected in corresponding overall species diversity. The results are presented in Figs. 1 and 2. The ecological models often result in multiple optima. With a given site constraint, there may be several alternative conservation networks available, which cover the same number of indicator species. In that case, our results include the average of (all) the species representations of these solutions.

Fig. 1 represents the number of species in the selected network compared to benchmark selection for chosen indicator species groups, plotted as a function of the number of protected sites. The stands were selected by using the EDIV model (complementarity approach). Beetles and vascular plants seem to be the best indicators because by using these groups, the selected networks also cover most of the other species. Understandably, beetles cannot be a poor indicator group, when economic costs are ignored, because about 68% of the species are beetles in our sample and the aim is to maximize species richness.

Fig. 2. Mean species representation (%) of the taxonomic group indicators compared to the benchmark model (=100), plotted as a function of the number of protected sites, based on the ENUM model.
Vascular plants are a good indicator group because spruce mires and herb-rich forests are the most important forest types in ecological optimisation for all species, and these types have a high diversity of vascular plants (cf. vascular plants in Pharo et al., 2000). Birds and the old-growth forest indicator species seem to perform the worst as overall indicators of total species richness.

It is not straightforward to rank the species groups because their operative ranges vary. For example, birds are fully covered by protecting six sites (Fig. 1). Thus, it is not possible to set priorities for sites by using birds if we want to protect more than six sites. Therefore, we cannot compare birds with other indicators when over six sites are selected. This problem can be avoided by using the ENUM models (e.g., scoring approach), where species presence is still kept track of even if all the species in a particular group are included into the network. The results based on the ENUM model are represented in Fig. 2. Areas selected by using the indicator species criteria seem to cover less species in total than the areas picked by the benchmark selection, as in the previous results considering the EDIV models. Moreover, the EDIV and ENUM models result in the same ranking of the indicator species (cf. Figs. 1 and 2). Interestingly, the scoring model, however, outperforms the complementarity model for birds and old-growth forest indicator species, the groups in which the number of species are the smallest.

4. The cost efficiency of indicator species

The ecological test does not consider the differences in the inventory and opportunity costs between alternative indicators; thus, we next incorporate these into the analysis. We start by considering how well they perform in terms of species protection when species inventory costs are omitted from the analysis. Then, we compare the indicators in terms of conservation costs, also taking inventory costs into consideration.

Fig. 3a–d represents the number of species in the selected network compared to the benchmark for the alternative indicator species group, plotted as a function of opportunity costs. The results are based on the IDIV model. Clearly, IDIV models usually cover all the species less than the benchmark model at any fixed budget level, when inventory costs are excluded from the consideration. However, the species loss is minor, when beetles are used as the target group in optimisation (Fig. 3a). On the average, calculated over the whole operative range of beetles by varying the budget, species loss is less than 1%. Unfortunately, beetles are a poorly known taxonomic group, and they have been rarely inventoried, so that it may be impossible to avoid inventory costs in practice. The selection based on vascular plants seems to also protect most of the other species (Fig. 3b). By using vascular plants in the IDIV model, it is on the average possible to cover almost 96% of all the species of the benchmark model. The mean species coverage is about 91% when using wood-inhabiting fungi as a target (Fig. 3c). Birds (Fig. 3a) and old-growth forest indicator species (Fig. 3d) seem to perform less well as overall indicators of total species richness. The average coverage regarding birds attains to 85% and the mean value for old-growth forest indicator species is about 84%. These results are similar to the results of ecological tests, indicating that the differences in the opportunity costs between indicators do not have a strong affect on their ranking (cf. Figs. 1–3).

An interesting view can be obtained by considering the operative range of each indicator. The operative range of vascular plants in the IDIV model ends when the budget is about 50,500 € and all vascular plants are covered in the selected network (Fig. 3b). However, there still are many unprotected stands left, which cannot be selected by using the vascular plants indicator. It costs almost 134,500 € to protect all of the 32 stands without considering inventory costs. Also, birds (Fig. 3a), wood-inhabiting fungi (Fig. 3c), and old-growth forest indicator species (Fig. 3d) have a rather narrow operative range because their number of species is relative small. It is noteworthy that the

---

6 The operative range of an indicator is the range of conservation costs or number of sites, in which the indicator species are not all represented in the selected conservation network. After the indicator species are fully represented, the remaining unprotected stands cannot be selected by using the indicator.

7 The effectiveness of the EDIV and ENUM models can be compared only in the range where EDIV model is operative. The ENUM model is inevitably relatively effective when the majority of the stands is protected.
operative range of wood-inhabiting fungi (64 spp.) is larger than that of vascular plants (103 spp.), although the latter group has more species. This indicates that wood-inhabiting fungi species are a relatively demanding group from conservation perspective, as covering all the species in this group requires some 90,000 €.

Next, we assess the indicators from the conservation cost point of view. Fig. 4 gives the absolute costs of conservation in terms of the cost functions of the

![Fig. 3. Relative number of species represented (=1 - (Y_bench - Y_ind)/Y_bench)*100) in the selected conservation network, plotted as a function of opportunity costs, based on the IDIV model excluding inventory costs using (a) beetles and birds, (b) vascular plants, (c) wood-inhabiting fungi, and (d) old-growth forest indicator species.](image1)

![Fig. 4. Conservation costs plotted as a function of the number of species represented in the selected conservation network, based on the IDIV model using (a) benchmark (all species) and birds, (b) beetles and vascular plants, (c) wood-inhabiting fungi, (d) old-growth forest indicator species.](image2)
The cost functions include two parts, the inventory costs and opportunity costs of conservation. Because the inventory costs are independent of the level of conservation, at low levels of conservation, the share of inventory costs from total costs is high, and they may dominate the cost pattern. This is clearly the case when we consider the benchmark or the costs of using beetles (Fig. 4a) or old-growth forest indicator species (Fig. 4d) as an indicator group. In other groups, the inventory costs do not seem to have strong effects on cost functions. Especially at a low level of conservation, the absolute cost difference between the benchmark model and the IDIV models for vascular plants (Fig. 4b), wood-inhabiting fungi (Fig. 4c), and birds (Fig. 4a) is rather big. It is typical for all the models that the opportunity costs increase exponentially as the species coverage increases, e.g., the marginal costs of conservation are increasing. However, we can note that the cost functions of the indicator models are not increasing all the time because they were not optimised in terms of all species coverage in contrast to the benchmark model. If a particular species group is a poor indicator, its use will increase the opportunity costs of conservation relative to better indicators; however, this is difficult to notice in terms of absolute costs.

In order to rank the indicators, we calculated the relative cost differences between indicator models (IDIV) and the benchmark in Table 3. Vascular plants seem to be the best indicator group from a relative cost point of view. The mean cost difference between the benchmark and vascular plants is bigger than the differences for other groups at every level of species represented. On the average, the conservation costs are about 68% larger in the benchmark case than using vascular plants as an indicator group in the operative range of vascular plants. The old-growth forest indicator species are surprisingly the poorest surrogate measure, as their mean cost difference is the lowest. The protection decisions based on old-growth forest indicator species incur even more costs than the benchmark when the range of species represented is 61–80%. Beetles also have a low mean cost difference, 14%. The figure for wood-inhabiting fungi is 56%. Birds, as indicators, are operative only within a narrow range of conservation (the maximum species representation is less than 71% of the total) because the number of bird species is small and all birds become included at a relatively low level of conservation and therefore provide no information for site selection procedures thereafter. A general pattern in the results is that the wider the operative range of an indicator, the smaller the cost difference is because of fixed inventory costs. Consequently, the average cost difference of birds is the highest at 79%, but birds are clearly an inferior indicator group relative to vascular plants.8

In Table 4 are the relative cost differences between the INUM models and the benchmark. Interestingly, the scoring procedure seems to be more effective than the complementarity models in representing all species (cf. Tables 3 and 4). Only

---

8 We compared indicators also to benchmark, which does not include inventory costs. In that case, the rank according to mean cost difference was vascular plants, wood-inhabiting fungi, birds, beetles, and old-growth forest indicator species in descending order (the detailed results are available from the authors).
for beetles, where the number of species is rather high, is the INUM model poorer than the IDIV model. According to the INUM optimisations, birds are the best indicators, and vascular plants are almost as good as birds. Beetles and old-forest indicators are the poorest indicators.

5. Assessing the results

Our analysis suggests that using indicator species may result in a loss of overall biodiversity (see Flather et al., 1997; Oliver et al., 1998; Van Jaarsveld et al., 1998; Chase et al., 2000; Reyers et al., 2000). In contrast, Virolainen et al. (2000) found that the use of one taxonomic group captured the species richness of all groups with the same efficiency as using information on all taxa at once in taiga forests. Howard et al. (1998) had similar findings from a tropical forest in Uganda. However, Virolainen et al. (2000) and Howard et al. (1998) used a heuristic optimisation procedure, and therefore, there is no guarantee that optimal solutions were found (see Pressey et al., 1997). Our findings support the statement made by Howard et al. (1998) that temperate (and also boreal) regions may be too homogenous and relatively species poor, and therefore, complementary areas for indicator taxon may not capture diversity in other groups. Also, in Virolainen et al. (2000), the considered areas were very heterogeneous, including 16 old-growth forests from Finland and Sweden, which were situated on islands or in the mainland.

However, in our case, the use of indicators usually costs less than the benchmark, except with the old-growth forest indicator species, suggesting that a wide inventory of species is not cost-efficient. Whether this result can be generalized is an open question. We have a small number of stands and we treated the stands as having equal sizes in the optimisations. The contribution of inventory costs to total expenditure would be minor if the number (or area) of protected stands, i.e., opportunity costs, was larger. In that case, we would likely see more clear tradeoffs in benefits between the use of indicators and large-scale species inventory. The use of an indicator costs less than extensive species inventories at a low level of conservation, but at a higher level, such inventories may be reasonable by reducing the opportunity costs of conservation due to a more efficient selection of protected areas (Balmford and Gaston, 1999).

Ecological models lead to a different ranking of indicators compared with the integrated models; thus, it is very important to include opportunity and inventory costs into the analysis. However, according to our findings, there seems to be no indicator group which would be unambiguously better than any other group. Beetles turned out to be a good indicator group relative to the other groups at a high level of conservation, despite the high inventory costs. Thus, it may be reasonable to execute an expensive inventory for beetles when the task is to complement a large existing conservation network which already covers less species-rich taxa. Beetles are good indicators also in the absence of inventory costs. These results support the view that the inclusion of invertebrates into biodiversity surveys may offer cost savings (see Oliver et al., 1998). Vascular plants seem to be the best indicator, although they are not usually consid-

The last row includes the mean cost difference calculated over the whole range, where the particular indicator is operative. The mark (–) indicates the range, where the indicator is not operative.
ered as a potential indicator group for species diversity in boreal old-growth forests, because usually, vascular plant diversity is low in coniferous boreal forests (Esseen et al., 1997). One explanation for our findings might be the fact that the diversity of vascular plants is highest in stands with the lowest opportunity costs (spruce mires forest type, see Juutinen et al., in press, see also Section 3). Birds are also relatively good indicators when the selection of protected stands is based on the INUM model. Inventory costs are low, and scoring algorithms ensure that enough information is available for ranking all stands despite of the low number of species of birds. Wood-inhabiting fungi seem to be a rather demanding group to protect, and it is a rather poor indicator for overall species diversity. Also, the so-called old-growth forest indicator species are relatively poor indicators for all species richness. It is likely that low species richness, combined with relatively high inventory costs, reduces the effectiveness of this group.

We treated all species as equally important in the benchmark, assuming that the aim of conservation is to protect all naturally occurring species in the region. However, threatened and rare species are often primary targets in conservation (e.g., Kershaw et al., 1995) and it is possible that wood-inhabiting fungi and old-growth forest indicator species would be better indicators for threatened and rare species than for overall species diversity. Also, population viability is an important aspect of conservation (Cabeza and Moilanen, 2001). Viability is a function of the number of individuals, and therefore, the abundance of species in addition to their presence/absence could be used as a surrogate measure (e.g., Montgomery et al., 1999; see also Noss, 1999). However, here we may end up with similar problems as with presence/absence data that the viability of one species populations may not be a reliable indicator of overall species viability. Our ecological knowledge is far too limited for identifying such umbrella species, whose viability would ensure the persistence of species diversity more generally. An example of one potential umbrella species in boreal forests is the white-backed woodpecker. Martikainen et al. (1998) found that the presence of the woodpecker clearly indicated high species richness of threatened beetle species as well.

According to our results, the scoring models (NUM) were generally better than the models based on complementarity (IDIV) in representing all species. In contrast, previous studies have suggested that the scoring procedure results in biased conservation because redundant sites may become selected (Pressey and Nicholls, 1989; Sætersdal et al., 1993). However, our approach differs from fixed scoring because we also considered conservation costs and the allowable budget for conservation. When scoring models include a budget constraint, they seem to have properties similar to the integrated complementarity models, which take the species composition of the stands into account (see Juutinen et al., in press).

Given that the use of an indicator seems to result in a loss of overall diversity, this also brings up many important general issues. Is the loss real? Our ecological knowledge is incomplete and we are dealing with several measurement problems. If the loss is likely, are we ready to accept it and consider the tradeoffs between biodiversity benefits and other benefits? Assessing these questions involves value judgments, which reflect social preferences for ecological risks and biodiversity benefits versus the costs of conservation.

6. Summary and conclusions

We tested how effective species indicators are for all species diversity by using both an ecological (E) and integrated (I) approach. Moreover, we used models based on complementarity (DIV) and scoring (NUM). Our main conclusion is not too positive: there seems to be fairly few alternatives for a complete inventory of biodiversity if the goal is to maintain populations of all species in the landscape. The use of site selection based on individual

---

9. Regional studies in Australia, South Africa, and the United States have also found that vascular plants may be a useful indicator taxon (Pantzer and Schwartz, 1998; Pharo et al., 2000; Reyers et al., 2000).

10. Respectively, Reyers et al. (2000) found that in South Africa, birds were a better indicator group in hot spot selection than in complementary selection, although the number of bird species was the largest among the considered taxonomic groups (birds, butterflies, mammals, and vascular plants).
taxonomic groups or species set of old-growth forest indicator species seems to result in a loss of overall biodiversity (Pantzer and Schwartz, 1998; Pharo et al., 2000; Reyers et al., 2000; Virolainen et al., 2000). Therefore, it is very important to consider tradeoffs between conservation costs and diversity loss when assessing the goodness of an indicator.

Considerable conservation costs may be incurred from using surrogate measures, although the use of indicators seems to cost less than a broad species inventory for optimisation in our small case study. More studies, however, are needed to reveal whether, in general, it is more beneficial to use an indicator or to execute a broad species inventory (cf. Balmford and Gaston, 1999). According to our findings, vascular plants and birds are the most cost-efficient indicators for species diversity in boreal old-growth forests in the given region, particularly if the INUM model is used for the site selection. This is partly because obtaining data for these species groups is relatively cheap. Thus, they may be suitable indicators for overall species diversity to be used in landscape ecological forest management.

The results demonstrated that the efficiency of a considered indicator is dependent on several factors, and therefore, the comparison between indicators is not straightforward. First, inventory costs strongly affect efficiency. In general, small inventory costs result in high efficiency. In practice, inventory costs can vary widely due to the different sampling methods (Balmford et al., 1996; Oliver and Beattie, 1996; Howard et al., 1998; Lawton et al., 1998; Oliver et al., 1998). Second, the use of an indicator may increase the opportunity costs of conservation compared with cost-effective protection. However, this may vary at different budget levels (cf. Balmford and Gaston, 1999). Third, the optimisation procedure also affects the results (cf. Reyers and Van Jaarsveld, 2000). The scoring approach (NUM) was suitable for small taxonomic groups and the complemenarity model (DIV) for large species groups. Overall, the results support the view that the selection of an indicator depends ultimately on the goals and the constraints of a conservation study (Caro and O’Doherty, 1999; Reyers et al., 2000; Reyers and Van Jaarsveld, 2000). It is therefore very important to set explicit goals in the forest planning process (see Noss, 1999).

Finally, we caution against straightforwardly generalizing our results to other regions and forest areas but emphasize the need for local knowledge on species composition and ecological conditions. Moreover, species richness is just one aspect of biodiversity, and in practice, also the other aspects should be considered. An interesting broad-scale approach, for example, could be the use of ecosystem types as indicators of biodiversity due to the available rapid assessment methods, e.g., the use of satellite image information in conjunction with ordination models (see Faith et al., 2003). In general, we should develop cheaper sampling methods particularly for taxa having a large number of species, such as beetles. We stress the importance of taking opportunity and inventory costs into account if the aim is cost-effective protection. To assess the opportunity costs, one may also need to consider other options than clear cutting, e.g., selective harvesting, and other than timber values, such as recreational services. Incorporating these aspects may result, however, in a more complex nonlinear problem which cannot be solved via stepwise linear bundling, but special algorithms developed for nonlinear problems may be needed. To conclude, we developed in this paper a method for testing biodiversity indicators in the ecological and economic context simultaneously and recommend that this integrated approach would be used instead of the mere ecological tests used previously.

Appendix A. Pattern of species representation in the selected network, plotted as a function of the opportunity costs, based on the benchmark model (IDIV)

Appendix B. The notation used in Table 1

\[ Z \]
Surrogate biodiversity measure

\[ j, J \]
Index and set of potential reserve sites

\[ x_j \]
1 if stand \( j \) is selected and 0 otherwise

\[ i, Z \]
Index and set of species in the indicator model

\[ y_i \]
1 if species \( i \) is contained in at least one of the selected stands and otherwise 0

\[ y_{ij} \]
1 if species \( i \) is contained in the stand \( j \) and otherwise 0

\[ N_i \]
The subset of candidate reserve stands that contains species \( i \)

\[ k \]
Number of sites allowable for reserve network

\[ B \]
Budget allowable for reserve network

\[ b_j \]
Opportunity costs of establishing a reserve stand \( j \)

\[ I_s \]
Inventory costs of surrogate measure
